Ohio State Faculty Lunch  
November 9, 2020

A DSGE model with recursive utility, search frictions, and capital accumulation is a good start to explaining the equity premium puzzle, while retaining plausible business cycle dynamics

Explaining the Mehra-Prescott (1985) equity premium puzzle in general equilibrium production economies has been challenging

- Rouwenhorst (1995); Jerman (1998); Tallarini (2000)

Finance specifies “exotic” preferences and exogenous cash flow dynamics to match asset prices, while ignoring firms

- Campbell and Cochrane (1999)
- Bansal and Yaron (2004)
- Rietz (1988); Barro (2006)

Macroeconomics analyzes full-fledged DSGE models, while ignoring asset prices with primitive preferences

- Christiano, Eichenbaum, and Evans (2005)

# Introduction

The holy grail of macro-finance:  
A unified theory of asset prices and business cycles

What are the microfoundations for the exogenous, often complicated cash flow dynamics in finance models?

To what extent do time-varying risk premiums matter quantitatively for macroeconomic dynamics?

How large is the welfare cost of business cycles in a general equilibrium production economy that replicates the equity premium?

Calibrated to the consumption volatility in the Jordà-Schularick-Taylor database, the DSGE model yields a (leverage-adjusted) equity premium of **4.26%** per annum, an average interest rate of **1.59%**, and a stock market volatility of **11.8%**

Strong time series predictability for stock market excess returns and volatilities, some predictability for consumption volatility, and weak to no predictability for consumption growth and real interest rate

Investment absorbs a large amount of shocks, making consumption growth and the interest rate unpredictable

Wage inertia: a wage elasticity to labor productivity of 0.256 in the model vs. **0.267** in the historical U.S. 1890–2015 sample

Risk aversion strongly affects quantity dynamics

Downward-sloping term structures of equity return and volatility

A timing premium of 15.3%

The welfare cost is huge, 28.7%, and strongly countercyclical

Petrosky-Nadeau, Zhang, and Kuehn (2018) on endogenous disasters, but limited asset pricing results (no capital)

Bai (2020) on the credit spread puzzle

Gourio (2012): The Rietz-Barro disasters in an RBC model

A representative household pools income from its employed and unemployed workers before making optimal consumption decisions

A representative firm makes optimal investment and vacancy decisions to maximize its market equity

The labor market as a matching function that yields new hires from the numbers of vacancies and unemployed workers

Wages determined from a generalized Nash bargaining process between the firm and unemployed workers

The household maximizes recursive utility,  $J_t$ :

$$J_t = \left[ (1 - \beta) C_t^{1 - \frac{1}{\psi}} + \beta \left( E_t \left[ J_{t+1}^{1 - \gamma} \right] \right)^{\frac{1 - 1/\psi}{1 - \gamma}} \right]^{\frac{1}{1 - 1/\psi}}$$

in which  $C_t$  is consumption,  $\beta$  time preference,  $\psi$  the elasticity of intertemporal substitution, and  $\gamma$  risk aversion

The household's stochastic discount factor,  $M_{t+1}$ :

$$M_{t+1} \equiv \beta \left( \frac{C_{t+1}}{C_t} \right)^{-\frac{1}{\psi}} \left( \frac{J_{t+1}}{E_t \left[ J_{t+1}^{1 - \gamma} \right]^{\frac{1}{1 - \gamma}}} \right)^{\frac{1}{\psi} - \gamma}$$

The representative firm uses capital,  $K_t$ , and labor,  $N_t$ , to produce output,  $Y_t$ , with the CES production function (Arrow et al. 1961):

$$Y_t = X_t \left[ \alpha \left( \frac{K_t}{K_0} \right)^\omega + (1 - \alpha) N_t^\omega \right]^{\frac{1}{\omega}}$$

in which  $\alpha$  is the distribution parameter, and  $e \equiv 1/(1 - \omega)$  the elasticity of substitution between capital and labor

The “normalized” CES function, the scalar  $K_0 > 0$  makes the unit of  $K_t/K_0$  comparable to  $N_t$  (Klump and La Grandville 2000)

Calibrate  $K_0$  to match  $1 - \alpha$  to the average labor share in the data

Aggregate productivity,  $X_t$ , with  $x_t \equiv \log(X_t)$  governed by:

$$x_{t+1} = (1 - \rho_x)\bar{x} + \rho_x x_t + \sigma_x \epsilon_{t+1},$$

in which  $\bar{x}$  is unconditional mean,  $0 < \rho_x < 1$  persistence,  $\sigma_x > 0$  conditional volatility, and  $\epsilon_{t+1}$  an i.i.d. standard normal shock

Scale  $\bar{x}$  to make the average marginal product of labor around one in simulations to ease the interpretation of parameters

The Den Haan-Ramey-Watson (2000) matching function,  $\iota > 0$ :

$$G(U_t, V_t) = \frac{U_t V_t}{(U_t^\iota + V_t^\iota)^{1/\iota}}$$

$\theta_t \equiv V_t/U_t$ ; the vacancy filling rate:  $q(\theta_t) = (1 + \theta_t^\iota)^{-1/\iota}$

Employment,  $N_t$ , evolves as:

$$N_{t+1} = (1 - s)N_t + q(\theta_t)V_t$$

in which  $q(\theta_t)V_t$  is the number of new hires

Vacancy costs:  $\kappa V_t$ , in which  $\kappa > 0$

Capital accumulates as:

$$K_{t+1} = (1 - \delta)K_t + \Phi(I_t, K_t),$$

in which  $\delta$  is the capital depreciation rate,  $I_t$  is investment, and

$$\Phi_t \equiv \Phi(I_t, K_t) = \left[ a_1 + \frac{a_2}{1 - 1/\nu} \left( \frac{I_t}{K_t} \right)^{1-1/\nu} \right] K_t$$

is the installation function with the supply elasticity of capital  $\nu > 0$

Set  $a_1 = \delta/(1 - \nu)$  and  $a_2 = \delta^{1/\nu}$  to ensure no adjustment costs in the deterministic steady state (Jermann 1998)

The equilibrium wage rate from Nash bargaining,  $W_t$ :

$$W_t = \eta \left( \frac{\partial Y_t}{\partial N_t} + \kappa \theta_t \right) + (1 - \eta)b$$

in which  $\eta \in (0, 1)$  is the workers' relative bargaining weight;  $b$  the workers' flow value of unemployment

$\eta$  governs the wage elasticity to labor productivity

The dividends to the firm's shareholders given by:

$$D_t = Y_t - W_t N_t - \kappa V_t - I_t$$

Taking  $W_t$ ,  $M_{t+1}$ , and  $q(\theta_t)$  as given, the firm chooses optimal investment and vacancies to maximize:

$$S_t \equiv \max_{\{V_{t+\tau}, N_{t+\tau+1}, I_{t+\tau}, K_{t+\tau+1}\}_{\tau=0}^{\infty}} E_t \left[ \sum_{\tau=0}^{\infty} M_{t+\tau} D_{t+\tau} \right],$$

subject to employment and capital accumulation and  $V_t \geq 0$

The competitive equilibrium consists of investment,  $I_t$ , vacancy posting,  $V_t$ , multiplier,  $\lambda_t$ , and consumption,  $C_t$ , such that:

- (i)  $C_t$  satisfies the consumption Euler equation;
- (ii)  $I_t$  satisfies the investment Euler equation, and  $V_t$  and  $\lambda_t$  satisfy the intertemporal job creation condition and the Kuhn-Tucker conditions, while taking the stochastic discount factor,  $M_{t+1}$ , and the equilibrium wage,  $W_t$ , as given;
- (iii) the goods market clears:

$$C_t + \kappa V_t + I_t = Y_t$$

From the first-order conditions for  $I_t$  and  $K_{t+1}$ :

$$\frac{1}{a_2} \left( \frac{I_t}{K_t} \right)^{1/\nu} = E_t \left[ M_{t+1} \left[ \frac{\partial Y_{t+1}}{\partial K_{t+1}} + \frac{1}{a_2} \left( \frac{I_{t+1}}{K_{t+1}} \right)^{1/\nu} (1 - \delta + a_1) + \frac{1}{\nu - 1} \frac{I_{t+1}}{K_{t+1}} \right] \right]$$

Equivalently,  $E_t[M_{t+1}r_{K_{t+1}}] = 1$ , in which the investment return:

$$r_{K_{t+1}} \equiv \frac{\partial Y_{t+1}/\partial K_{t+1} + (1/a_2)(1 - \delta + a_1) (I_{t+1}/K_{t+1})^{1/\nu} + (1/(\nu - 1))(I_{t+1}/K_{t+1})}{(1/a_2) (I_t/K_t)^{1/\nu}}$$

Let  $\lambda_t$  be the multiplier on  $q(\theta_t)V_t \geq 0$ , Kuhn-Tucker conditions:

$$q(\theta_t)V_t \geq 0, \quad \lambda_t \geq 0, \quad \text{and} \quad \lambda_t q(\theta_t)V_t = 0$$

From the first-order conditions with respect to  $V_t$  and  $N_{t+1}$ :

$$\frac{\kappa}{q(\theta_t)} - \lambda_t = E_t \left[ M_{t+1} \left[ \frac{\partial Y_{t+1}}{\partial N_{t+1}} - W_{t+1} + (1-s) \left( \frac{\kappa}{q(\theta_{t+1})} - \lambda_{t+1} \right) \right] \right]$$

Equivalently,  $E_t[M_{t+1}r_{N_{t+1}}] = 1$ , in which the hiring return:

$$r_{N_{t+1}} \equiv \frac{\partial Y_{t+1}/\partial N_{t+1} - W_{t+1} + (1-s)(\kappa/q(\theta_{t+1}) - \lambda_{t+1})}{\kappa/q(\theta_t) - \lambda_t}$$

The stock return of the representative firm,  $r_{St+1}$ , as a weighted average of the investment and hiring returns:

$$r_{St+1} = \frac{\mu_{Kt}K_{t+1}}{\mu_{Kt}K_{t+1} + \mu_{Nt}N_{t+1}}r_{Kt+1} + \frac{\mu_{Nt}N_{t+1}}{\mu_{Kt}K_{t+1} + \mu_{Nt}N_{t+1}}r_{Nt+1},$$

The shadow value of capital,  $\mu_{Kt} = (1/a_2)(I_t/K_t)^{(1/\nu)}$

The shadow value of labor,  $\mu_{Nt} = \kappa/q(\theta_t) - \lambda_t$

# The Model

Globally nonlinear projection with parameterized expectations  
(Petrosky-Nadeau and Zhang 2017)

Parameterize the conditional expectation in job creation condition

Solve for the indirect utility, investment, and conditional expectation functions from recursive utility, investment Euler equation, and job creation condition

Rouwenhorst discrete state on productivity with 17 grid points

Finite element with cubic splines on 50 employment nodes and 50 capital nodes; tensor product on each grid point of productivity

Solve the resulting system of 127,500 equations with the derivative-free fixed point iteration with a small damping parameter

U.S. historical monthly series: Unemployment and labor productivity, 1890–; vacancy, 1919–

Private nonfarm unemployment rates (Lebergott 1964; Weir 1992):  
Mean, 8.94%; volatility: 24.43% per quarter

$\theta_t$  volatility: 61.62% (but 38.38% with log deviations)

The  $U$ - $V$  correlation:  $-0.57$

Time discount factor,  $\beta = 0.9976$

Risk aversion,  $\gamma = 10$

Elasticity of intertemporal substitution,  $\psi = 2$

Persistence in log productivity,  $\rho_x = 0.95^{1/3}$

Calibrate its conditional volatility,  $\sigma_x = 0.015$ , to hit average  $\sigma_C$

Long-run mean of log productivity,  $\bar{x} = 0.1887$ , to target the marginal product of labor to be one on average

Elasticity of capital-labor substitution,  $e = 1/(1 - \omega) = 0.4$ , per Chirinko and Mallick (2017)

The distribution parameter,  $\alpha = 0.25$ , to match the average labor share of 0.743 per Gollin (2002)

The capital scalar,  $K_0 = 13.75$ , to target the labor share of 0.75 at the deterministic steady state (close to its stochastic steady state)

Supply elasticity of capital,  $\nu = 1.25$

Depreciation rate of capital,  $\delta = 1.25\%$

Separation rate,  $s = 3.5\%$ , the average in JOLTS

Curvature in the matching function,  $\iota = 1.25$  (Den Haan, Ramey, and Watson 2000)

Bargaining weight of workers,  $\eta = 0.015$

Flow value of unemployment,  $b = 0.91$ , a simple device for small fundamental surplus, see also Ganong, Noel, and Vavra (2020)

Unit vacancy cost,  $\kappa = 0.01$

The low- $\eta$ -high- $b$  calibration yields a wage elasticity to labor productivity of **0.256**

Hagedorn and Manovskii (2008) estimate the wage elasticity to be 0.449 in the postwar 1951–2004 quarterly sample from BLS

From 1929 to 2015, obtain compensation of employees from NIPA Tables 6.2A–D (line 3, private industries, minus line 5, farms)

Obtain the number of full-time equivalent employees from NIPA Tables 6.5A–D (line 3, private industries, minus line 5, farms)

Dividing the compensation of employees by the number of employees yields nominal wage rates (compensation per person)

Deflate nominal wage rates with the personal consumption deflator from NIPA Table 1.1.4 (line 2) to obtain real wage rates

From 1890 to 1929, obtain the average (nominal) hourly compensation of production workers in manufacturing and consumer price index from [measuringworth.com](http://measuringworth.com) (Officer 2009, Table 7.1; Officer and Williamson 2020a, 2020b)

Divide the manhours index by the index of persons engaged in manufacturing from Kendrick (1961, Table D-II) to obtain hours

Multiply the average hourly compensation series with the hours index to obtain the nominal compensation per person; deflate with the Officer-Williamson consumer price index to obtain real wages

Splice this series in 1929 to the NIPA series from 1929 onward to yield an uninterrupted series from 1890 to 2015

Historical 1890–2015 series of labor productivity from Petrosky-Nadeau and Zhang (2020)

Time-aggregate monthly series into annual by taking the monthly average within a given year

Detrend the annual real wages and labor productivity series as log deviations from their HP-trends with a smoothing parameter of 6.25

In our postwar 1950–2015 annual sample, regressing the log real wages on the log labor productivity yields a wage elasticity of **0.406**, with a standard error of 0.081

In our 1890–2015 sample, the wage elasticity estimated to be **0.267**, with a standard error of 0.066

Core challenge in explaining the equity premium in production economies (Kaltenbrunner and Lochstoer 2010): Dividends tend to be countercyclical in RBC models

- Dividends = profits (output minus wages) minus investment
- With frictionless labor market, wages equal MPL (as procyclical as output)
- Profits no more procyclical than output
- Investment more procyclical than output and profits (consumption smoothing)
- Dividends tend to be countercyclical

The search model overcomes the core challenge in explaining procyclical dividends in general equilibrium production economies

- Dividends = profits (output minus wages) minus investment minus vacancy costs
- With search frictions, wages are inertial, detached from MPL
- Profits more procyclical than output
- Investment (and vacancy costs) more procyclical than output (consumption smoothing)
- Profits more procyclical than investment and vacancy costs, giving rise to procyclical dividends

# Unconditional Moments

## Implied consumption dynamics in the search economy

Different consumption dynamics accord with observed (postwar) consumption moments but imply vastly different mechanisms

From 1-million months simulation from the model:

$$g_{Ct+1} = E_t[g_{Ct+1}] + \sigma_{Ct} \epsilon_{t+1}^g$$

$$E_{t+1}[g_{Ct+2}] = 0.288 E_t[g_{Ct+1}] + 0.705 \sigma_{Ct} \epsilon_{t+1}^e$$

$$\sigma_{Ct+1}^2 = 0.008^2 + 0.964(\sigma_{Ct}^2 - 0.008^2) + 0.421 \times 10^{-5} \epsilon_{t+1}^V,$$

in which  $g_{Ct+1}$  is realized consumption growth,  $E_t[g_{Ct+1}]$  expected consumption growth,  $\sigma_{Ct}$  conditional volatility of  $g_{Ct+1}$ , and  $\epsilon_{t+1}^g$ ,  $\epsilon_{t+1}^e$ , and  $\epsilon_{t+1}^V$  i.i.d. standard normal shocks

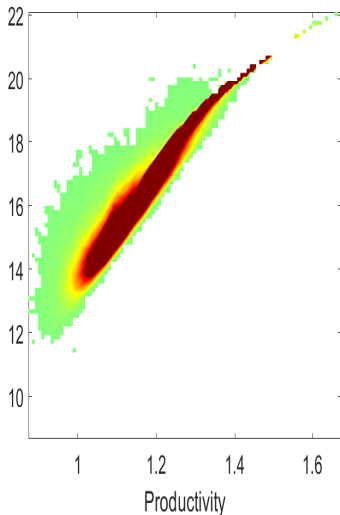

Pairwise correlations among  $\epsilon_{t+1}^g$ ,  $\epsilon_{t+1}^e$ , and  $\epsilon_{t+1}^V$  close to zero

Risk aversion,  $\gamma$ , matters for macroeconomic dynamics

A lower  $b$  yields lower macro volatilities, risks, and risk premiums

$\eta$  mostly affects the wage elasticity to labor productivity

A higher  $\kappa$  raises  $E[U]$  but reduces the equity premium

$\nu$  trades  $\sigma_C$  for  $\sigma_I$ , but leaving  $\sigma_Y$  unchanged

A lower  $\delta$  raises capital, reducing risks/risk premiums

A higher  $e$  raises macro volatilities, risks, and risk premiums

A higher  $\alpha$  downplays search frictions, reducing risks/risk premiums

Results insensitive to  $s$  and  $\iota$

Equity term structure, dividend strips, Binsbergen, Brandt, and Koijen (2012)

# Additional Implications

Equity term structure, consumption strips

## Additional Implications

The downward-sloping real yield curve, analogous to Nakamura et al. (2013)

Yield-to-maturity starts at 1.53% per annum for 1-month zero-coupon bond but falls to 1.29% for 1-year, 0.95% for 5-year, and further to 0.72% for 10-year bond

A yield spread of  $-0.81\%$  for the 10-year zero-coupon bond relative to the 1-month bond

The real term premium also negative,  $-1.11\%$ , for the 10-year zero-coupon bond

Disasters stimulate precautionary savings, drive down real interest rates, and push up bond prices (hedges against disasters)

## Additional Implications

Epstein, Farhi, and Strzalecki (2014): Investor sacrifices 31% of its consumption stream for early resolution of risks in Bansal and Yaron (2004) and 42% in Wachter (2013)

The timing premium,  $\pi \equiv 1 - J_0/J_0^*$ ,  $J_0$  is the utility with risks resolved gradually,  $J_0^*$  with risks resolved in the next period:

$$J_0^* = \left[ (1 - \beta) C_0^{1 - \frac{1}{\psi}} + \beta (E_t [(J_1^*)^{1 - \gamma}])^{\frac{1 - 1/\psi}{1 - \gamma}} \right]^{\frac{1}{1 - 1/\psi}}$$

in which the continuation utility  $J_1^*$ :

$$J_1^* = \left[ (1 - \beta) \sum_{t=1}^{\infty} \beta^{t-1} C_t^{1 - \frac{1}{\psi}} \right]^{\frac{1}{1 - 1/\psi}}$$

Calculate  $J_0^*$  via Monte Carlo simulations at the economy's stochastic steady state,  $\pi = 15.3\%$

## Additional Implications

The welfare cost of business cycles, Lucas (1987, 2003): 0.05%

${}_t C \equiv \{C_t, C_{t+1}, \dots\}$ : The consumption stream starting at  $t$

Calculate the welfare cost,  $\chi_t \equiv \chi(N_t, K_t, x_t)$ , implicitly from:

$$J({}_t C(1 + \chi_t)) = \bar{J} \quad \Rightarrow \quad \chi_t = \frac{\bar{J}}{J_t} - 1$$

in which  $\bar{J}$  is the recursive utility derived from the constant consumption at the deterministic steady state,  $\bar{C}$

Solve for  $\bar{J}$  by iterating on  $\bar{J} = \left[ (1 - \beta)\bar{C}^{1-\frac{1}{\psi}} + \beta\bar{J}^{1-\frac{1}{\psi}} \right]^{\frac{1}{1-\frac{1}{\psi}}}$

Average  $\chi_t$  in 1 million months simulation, **28.7%**

## Additional Implications

The welfare cost is strongly countercyclical,  $\text{Corr}(\chi_t, x_t) = -0.77$ ,  $\text{Corr}(\chi_t, U_t) = 0.92$ ;  
5th, 50th, and 95th percentiles: 17.5%, 24.6%, and 54.9%, respectively

A DSGE model with recursive utility, search frictions, and capital accumulation is a good start to explaining the equity premium puzzle, while retaining plausible business cycle dynamics

Future directions:

- Embed the model structure into a New Keynesian framework
- Extend the model to a multi-country setting
- Incorporate heterogeneous firms into our equilibrium model
